ABSTRACT

The inheritance patterns of the contrasting petal colour, purple and white; pod colour, purple and straw-white; and shoot colour, purple and green were studied. Analysis of the F_2 and backcross populations showed that petal colour is governed by one allelic pair WW, while pod and shoot colours appear to be determined pleiotropically by two allelic pairs, *PrPr* and *GrGr*, interacting in as recessive suppressors. The *PrPr* gene seems to be a set of localized alleles that determine the different purple colour intensities on pods. Deep purple pods are produced by the genotype *PrPr*; light purple by *Prpr*; and straw-white pods by prpr. Because *prpr* is capable of suppressing *Gr*- (recessive suppressor) the genotypes *prpr Gr*- produced normal green shoots or with very mild streaks of anthocyanin and straw-white pods. The genotypes *Pr*- *Gr*-, *Pr*- *grgr* and *prpr* grgr produced pigmented shoots and pods.

Key words: Colour, inheritance, cowpea, Vigna unguiculata.

Pigmentation is a common feature of most Nigerian vegetable cowpeas and its presence is due to the anthocyanin pigment. This soluble compound imparts purple colour on the shoot, pods and petals of cowpea. However, colour intensity on the pods tends to vary from very deep purple to light purple at full maturity and in dry pods.

Whereas any plant with purple shoot has purple pods, plants with purple petals may have either purple or green shoots in vegetable cowpea.

Inheritance studies on pigmentation in grain cowpea have been frequently made but similar studies on the vegetable cowpea are lacking in published literature. The present paper deals with the latter.

MATERIALS AND METHODS

Two accessions each of vegetable and grain cowpeas with the following characteristics were used in the study.

M. I. Uguru

$P_1 = AN-16-D$:	a vegetable cowpea with purple shoots, purple pods, and purple petals
P ₂ = AE-36-S:	a vegetable cowpea with green shoots, straw-white pods, and purple petals
P ₃ = AD-36-W _B :	a grain cowpea with green shoots, straw-white pods, and white petal
P4 = AD-36-W:	a grain cowpea with green shoots, straw-white pods, and purple petals

The seeds of these accessions were planted in small plots of 1.2×1.8 m each at the spacing of 90 x 30 cm [1]. Hybrid seeds (AE-36-S x AN-16-D) and (AD-36-W_B x AD-36-W) were produced by hand pollination using the method of Utuk [2]. The F₂ and F₃ generations were obtained by allowing natural self-pollination of the F₁ and F₂ populations, respectively. Backcrosses were made during flowering by crossing the F₁ hybrids with both parents. Numerical counts were made in the segregating populations to determine the inheritance pattern of different characters under investigation.

The χ^2 test was used to ascertain the goodness of fit to the expected phenotypic ratio.

RESULTS AND DISCUSSION

PETAL COLOUR

The F₂ plants resulting from the cross between the white flowered AD-36-W_B and the purple flowered AD-36-W had nearly intermediate (light purple) colour, so that the purple petal colour appeared to be partially dominant over the white petal colour. The F₂ population segregated into 44 purple : 102 light purple : 39 white (Table 1), a good fit to 1 purple : 2 light purple : 1 white ($\chi^2 = 2.2$, p > 0.10). A combination of the intermediate and the true purple colours gave another good fit to 3 purple : 1 white ($\chi^2 = 0.146$, p > 0.50). Further analysis on the assumption of a 15 purple : 1 white ratio did not show a good fit to the data ($\chi^2 = 64.96$, p < 0.01).

The backcross (AD-36-W_B x AD-36-W) x AD-36-W produced progeny with only purple petals, while the other backcross (AD-36-W_B x AD-36-W) x AD-36-W_B produced plants that segregated into 67 purple and 61 white petaled plants (Table 1). This is a good fit to 1 : 1 purple : white ratio ($\chi^2 = 0.28$, P > 0.50). The good fit to both 1 : 2 : 1 and 3 : 1 ratios stresses the need for a more critical evaluation of the results. The χ^2 value of 0.146 for perfect dominance is about 16 times lower than 2.22 obtained for incomplete dominance. This coupled with the considerable remoteness of the p value > 0.5 of the perfect dominance from p = 0.05 when compared to that of the incomplete dominance p > 0.1 confirms the 3 : 1

Inheritance of Pigmentation in Cowpea

381

M. I. Uguru

monohybrid ratio. Thus, one allele pair, WW, governs the inheritance of petal colour. The genotype WW produces purple, Ww relatively lighter purple, and ww white petals. The 3 : 1 monohybrid ratio is in agreement with earlier reports [3, 4].

POD AND SHOOT COLOURS

Table 2 shows joint segregation of pod and shoot colours in the F₂, F₃ and backcross populations. The F1 progeny of the cross AN-36-S x AN 16-D had pigmented shoot and pods, an indication of dominance of pigmented shoot over the nonpigmented [4]. All F_2 plants with purple shoots produced purple pods and the normal green plants produced straw-white pods. However, a few plants with mild streaks of anthocyanin on the shoot produced straw-white pods. This scheme tends to suggest that the genes governing pigmentation on shoots are the same as those which pleiotropically determine different purple shades on the pods [5]. The F_2 segregation ratio of 548 plants with pigmented shoots and pods: 116 plants with nonpigmented shoots and pods (Table 2) is a good fit to 13: 3 ratio ($\chi^2 = 0.714$, P > 0.10). Support for this scheme was obtained from the segregation pattern of 200 F3 families. Eighty-three F3 families bred true for purple shoot and pod; 108 segregated; and 9 bred true for green shoots and straw-white pods, a good fit to 7:8:1 ratio (χ^2 = 1.85, P > 0.10). The 13 : 3 ratio appears to implicate two separate loci as proposed by [6, 7]. However, the 13 : 3 ratio does not support duplicate gene action hypothesis of the former authors. Rather, it implicates a modifier gene interaction in the form of a recessive suppressor. Two allelic pairs, one major pair (GrGr) and a localized pair (PrPr) seem to interact and govern the inheritance of pigmentation on the cowpea shoots and pods. The localized alleles may, depending on the forms in which they are present, produce deep purple, light purple or straw-white pods. Deep purple pods are produced in dominant homozygous (PrPr) condition; light purple pods appear in the genotype PrPr, while straw-white pods are produced by the genotype prpr. Since prpr is capable of suppressing *Gr*- (recessive suppressor), the cowpea shoots with either green colour or mild streaks of anthocyanin produce straw-white pods. Both the shoots and pods were pigmented in the Pr– Gr–, Pr– grgr and prpr grgr genotypes.

In conclusion, the possible genotypes of the experimental strains may be represented as:

AN-16-D (pigmented shoots, pods and petals): *Pr*- *Gr*- *Wr*-, *Pr*- *grgr W*- and *prpr* grgr *W*-

AN-36-S (nonpigmented shoots and pods, and pigmented petals): prpr Gr-W-

AD-36-W (nonpigmented shoots and pods, pigmented petals): prpr Gr-W-

AD-36-WB (nonpigmented shoots, pods and petals): prpr Gr-WW.
